Isogenic lines of the tomato 'Ailsa Craig'

L. A. DARBY, D. B. RITCHIE AND I. B. TAYLOR

Introduction

The backcross method has been widely used for breeding new varieties of many crop species. It provides a convenient way to transfer simply-inherited characters from one variety or a wild species into an existing cultivar in order to make a particular improvement to it. The method can be used for any character which is under monogenic control; classic examples are those in which disease resistance factors have been transferred into varieties with good agronomic performance. Many of the parents of F_1 hybrid tomatoes bred at the Glasshouse Crops Research Institute have been produced by the backcross method.

Isogenic lines which result from backcross breeding have great potential for purposes other than variety improvement. In studies of gene action and biochemical pathways it is very useful to have different mutant alleles in a standard genotype, especially when quantitative assessments are being made. For genetical investigations, such as studies of linkage or of chromosome substitution, isogenic lines are preferable to material with diverse genetical backgrounds. Lines which contrast solely for specified loci provide excellent research material for workers in disciplines such as plant physiology or pathology. Isogenic lines also enable very critical assessments to be made of novel characters which might be of interest in relation to crop culture or consumer demand.

The cultivated tomato Lycopersicon esculentum Mill. and related wild species have been extensively studied genetically, and there is much information in the general literature. This is considerably supplemented by the Reports of the Tomato Genetics Co-operative (TGC) organized under the Chairmanship of Professor C. M. Rick at the Department of Vegetable Crops, University of California, U.S.A. A great feature of these Reports is the very speedy announcement of new mutants of tomato. Co-operative studies have enabled many of these mutants to be assigned to particular loci in the chromosome complement. Inevitably, because workers are usually involved with different varieties, the majority of the mutants are discovered and described in different genetic backgrounds.

A proposal that the mutant alleles should be transferred into separate lines of two contrasting standard tomato varieties was made in 1965 (Darby,

Rick

1965). It was suggested that one of these should be a small-fruited variety typical of those grown in glasshouses in north-west Europe, and the other a large-fruited field variety as grown in the lower latitudes of the U.S.A. It was felt that long-established varieties should be used rather than contemporary types, because the latter themselves often have Mendelian characters bred into them, and they are often surpassed and discarded quite quickly.

A programme was set up at the G.C.R.I. using 'Ailsa Craig' as the recurrent parent for the backcross pedigrees. Good progress has been made in the production of isogenic lines; these are described below. Professor L. Butler, in the University of Toronto, Canada, has also produced several isogenic lines of 'Ailsa Craig' in the course of his studies on chromosome 2 mutants. Unfortunately similar progress has not been made throughout North America, where agreement has not been reached on the standard variety to be used.

The cultivar Ailsa Craig

'Ailsa Craig' was selected from a cross between 'Fillbasket' and 'Sunrise' and was first introduced in 1910 (Lisman, 1961). Plants have vigorous indeterminate growth with a tall spreading habit. They produce long usually unbranched trusses which carry small (40–60 g) bilocular fruit which are slightly flattened rather than deep in vertical section. The fruits are very prone to greenback though in other respects colour quality is usually very good. Eating quality is always very well rated due to the variety's potential for high sugar and high acid content of the fruit.

Early yield is good because the fruits ripen quickly but their inevitable rapid softening precludes the use of the variety if marketing is long delayed after harvesting. Two faults of the variety are its particular susceptibility to leaf mould (*Fulvia fulvum*) and its tendency to produce "rogues", known also as "jacks", "male plants" or (more descriptively) "feather legs" or "Christmas trees".

'Ailsa Craig' is now virtually unused for commercial crop production, though its backcross derivative 'Craigella', to which the uniform ripening allele, u, confers freedom from greenback, is grown by amateur gardeners. However, the variety's general characters and its long history make it very suitable for use as the recurrent parent in the project described.

Production of the isogenic lines

The donor parents from which mutant alleles were transferred ranged from wild species to cultivated varieties. The majority contrasted quite markedly with 'Ailsa Craig'; their names, if known, are given in the descriptive list below (Table I). Each mutant allele was transferred into a separate line of the recurrent parent, at least five crosses being made with 'Ailsa Craig'. This gives a chance for 97 per cent recovery of the recurrent parent genotype, assuming that the selected plant in each cycle is chosen at random and that there are no counteracting linkage effects.

Mature plant characters determined by recessive alleles were usually manipulated by alternate backcrossing and selfing, twenty plants being grown in each of the segregating generations. This provided a modest opportunity to select for characters of the recurrent parent among the few plants found to be carrying the allele under transfer. Recessive characters which are manifest in the seedlings or young plants were transferred by repeated backcrossing with simultaneous selfing to reveal which line was carrying the desired allele. It was usual to base each cycle on eight parent plants. Dominant characters were transferred by repeated backcrossing followed by the two selfing generations necessary to establish homozygosity. At the conclusion of each backcross pedigree a single plant was selected as the basis of the new true-breeding line, which was then allocated a GCR number.

Propagation and comparison of the isogenic lines

The breeding of the isogenic lines has been spread over several years, but by 1977 sufficient lines had been produced to warrant their extensive testing. Seed of the 138 GCR lines listed below was sown on 24 May. This date ensured that the plants would be grown through a period when climatic conditions favoured fast growth and good development. They were given standard conditions for glasshouse tomato culture in terms of compost, watering, liquid feeding and temperatures. After propagation in 110 mm diam. "Whalehide" pots they were transferred to 250 mm diam. plastic pots on open benches when the first inflorescence was apparent. All plants were trained as a single staked stem and "stopped" two leaves above the third truss. Duplicate plants of each mutant were grown, and control plants of 'Ailsa Craig' were randomized throughout the experimental area. All plants were inspected regularly and formally examined for descriptive purposes at appropriate stages.

Results

The descriptions of the isogenic lines are listed in alphabetical order of the mutants in Table I; the supplementary Tables II-IV reclassify this information. Some examples of the isogenic lines are shown in Plates IA, IB.

Table I presents information about each mutant and its corresponding isogenic line. Each entry gives the mutant's symbol and name. An index number or letters attached to the symbol indicates an allele with different effect at the same locus e.g. ag, ag^2 and Wo, Wo^m and Wo^v . The original allele is not indexed. A hyphen and a number after the symbol indicates a mutant of similar effect at a different locus, e.g. Xa-2, Xa-3. In such cases the original locus is also shown numbered, e.g. Xa-1. The original reference to the character is provided as the number and page of the relevant TGC Report, e.g. TGC 23:13.

These entries are followed by details, when known, of the nature of the mutation, e.g. spontaneous (spon), induced by irradiation (irr) or by chemical treatment (chem), and the name of the variety or species in which the mutant was first found. Each description is based on a comparison of the isogenic line with 'Ailsa Craig'; relative plant height was assessed at three weeks from sowing. The descriptions are very general; it was quite impossible, because of the amount of material, to investigate the more subtle differences between mutant and wild type. These will have to be recorded from more detailed studies of individual lines, and this has been done for several of the fruit-colour mutants (Darby, 1978).

The "ch" number is that of the chromosome to which the mutant locus has been assigned. The "mc" number indicates the mutant's classification (see Table III). The "esv" number represents the earliest stage of plant growth at which the mutant is visible (see Table IV). The entry concludes with a GCR number, the Institute's code for the mutant line isogenic with 'Ailsa Craig'.

Table II lists the mutants allocated to each chromosome. Gene order can be found on the chromosome map published in TGC 27:5.

Table III presents the mutants classified into types according to the TGC system.

Table IV shows the mutants grouped by their esv number.

Discussion

The transfer of a large number of monogenically controlled characters into a standard genetic background by the backcross method may at first appear to be a straightforward process. However, more detailed consideration of the concept of the isogenic line reveals some obvious limitations and a subtle difficulty.

Close genetic linkage in the region of the locus being manipulated may create two major problems. The first results from the relationship between the donor and the recipient genotypes. A section of the chromosome adjacent to the allele being backcrossed will tend, depending on the position and frequency of cross-overs, to be transferred with it. If the donor and recipient are closely related, the chance of there being major genetic differences in the region of the locus will be small. However, the possibility of encountering problems of this type will rise considerably when the donor and recipient are members of different species.

The second linkage problem depends to some extent on the way in which mutations occur. Simultaneous spontaneous mutation at two loci is a rare event, but such changes are much more likely to take place when material is exposed to irradiation or chemical mutagens. Several generations of testing might be necessary before the true nature of such a dual change became obvious and, if the loci were closely linked, separate identification might be long delayed. The current tomato linkage map (TGC 27:5) and the mutant descriptions given here reveal some probable examples of "double mutants" in the 'Ailsa Craig' isogenic lines. Some examples follow:

The description for "compound inflorescence" (s) states that the fruit of this line are beaked. Examination of the linkage map for chromosome 2 reveals that the s locus maps at 30 units, while the bk locus (beaked fruit) maps at 38 units on the same chromosome. The donor parent used for the s transfer was a chromosome 2 marker stock which carried $d p \ s \ o \ bk$. The inadvertent retention of bk stresses the problem due to linkage, though it is possible that the growing of larger segregating populations and more intense selection against unwanted characters would probably have eliminated bk.

The fruit of 'Lax' (Lx) are described as elongated. Examination of the linkage map for chromosome 2 reveals that the Lx locus maps at 56 units while the o locus (ovate fruit) maps very closely at 55 units.

The characters described for the 'ripening inhibitor' (*rin*) line include a grossly enlarged calyx. The linkage map for chromosome 5 shows the *rin* locus at 0 units while the *mc* locus (macrocalyx) also maps at the same position. This association has been attributed to a small deletion involving closely linked loci, rather than simultaneous point mutations (Robinson & Tomes, 1968).

The genetic backgrounds of the species or varieties involved in a backcross programme may have a more insidious influence on the derived isogenic lines. Background genes in the donor parent and recurrent parent genomes may differentially affect some aspects of the mutant's expression. Thus, a description of a mutant phenotype in the original species or variety may not be totally applicable to a gene's expression in the genetic background of the recurrent parent. Consequently, when the mutant is being transferred by means of backcrossing, it is possible that severe selection for a detailed specification of the mutant's effect will result in a retention of the very modifiers which one is trying to eliminate. In order to try to overcome this difficulty it may be advisable to base selection on the one character which dominates the first recorded description of the mutant. Unfortunately this may be a rather subjective process, particularly when there are several major phenotypic changes.

In spite of the limitations outlined above, there is no doubt that the examination of mutant characters after backcrossing them into a common genetic background gives a more accurate estimate of their comparative effects than would otherwise be possible.

The repeated selection and selfing of heterozygotes derived from a cross between wild type and mutant lines, followed by ultimate separation into dominant and recessive types, is an alternative approach, though the method can only be applied to species which will tolerate repeated inbreeding. The two resulting lines will undoubtedly have similar genetic backgrounds, but the problems accruing from tight linkage will persist. One might handle a very few genes simultaneously within the same segregating family but the method would be quite impossible for the large number of mutants in the described work. If separate inbreeding programmes are conducted it is not possible to make accurate comparisons between mutants.

Perhaps the production of totally uniform series of isogenic lines awaits the development of techniques whereby a mutant gene can be physically removed from the genome of one variety and inserted, uncontaminated, into the genome of another.

Acknowledgements

We thank Professor C. M. Rick and many others who kindly supplied seed of tomato mutants, the nursery staff at the G.C.R.I., who have uncomplainingly grown very many strange tomato plants, and Miss Helen Featherstone for collating the data presented in the Tables.
